A dyadic endomorphism which is Bernoulli but not standard

Christopher Hoffman
Daniel Rudolph
June 19, 1999

Abstract

Any measure preserving endomorphism generates both a decreasing sequence of \( \sigma \)-algebras and an invertible extension. In this paper we exhibit a dyadic measure preserving endomorphism \( (X,T,\mu) \) such that the decreasing sequence of \( \sigma \)-algebras that it generates is not isomorphic to the standard decreasing sequence of \( \sigma \)-algebras. However the invertible extension is isomorphic to the Bernoulli two shift.

1 Introduction

Consider the one sided Bernoulli two shift. This transformation has state space \( X = \{0, 1\}^\mathbb{N} \) and \( (1/2, 1/2) \) product measure \( \mu \). The action on \( X \) is \( T(x)_i = x_{i+1} \). In this paper we consider two properties that the one sided Bernoulli two shift has and give an example of an endomorphism which shares one of these properties but not the other.

The first property is the decreasing sequence of \( \sigma \)-algebras that the one sided Bernoulli two shift generates. A decreasing sequence of \( \sigma \)-algebras is a measure space \( (X, \mathcal{F}_0, \mu) \), and a sequence of \( \sigma \)-algebras \( \mathcal{F}_0 \supset \mathcal{F}_1 \supset \mathcal{F}_2 \ldots \). Let \( \mathcal{F} \) be the Borel \( \sigma \)-algebra of \( X \) and let \( \mathcal{F}_i = T^{-i} \mathcal{F} \). This sequence has the property that for every \( i \) \( \mathcal{F}_i | \mathcal{F}_{i+1} \) has 2 point fibers of equal mass for every \( i \). A decreasing sequence of \( \sigma \)-algebras with this property (and an endomorphism which generates such a sequence) is called dyadic. This example has the property that \( \bigcap_i \mathcal{F}_i \) is trivial. A. Vershik, who began the modern study of such decreasing sequences of \( \sigma \)-algebras [8], refers to this example as the "standard dyadic" example. Any
measure preserving endomorphism \((X, T, \mathcal{F}, \mu)\) generates a decreasing sequence of \(\sigma\)-algebras by setting \(\mathcal{F}_i = T^{-i}\mathcal{F}\).

Two decreasing sequences of \(\sigma\)-algebras are called **isomorphic** if there exists a 1-1 measure preserving map between the two spaces that carries the \(i\)-th \(\sigma\)-algebras to each other. In [7] Vershik showed that there exist dyadic sequences of \(\sigma\)-algebras with trivial intersection that are not isomorphic to the standard dyadic example. In [7] Vershik also gave a necessary and sufficient condition for a dyadic decreasing sequence of \(\sigma\)-algebras to be standard. An equivalent description of standardness for dyadic sequences is for there to exist a sequence of partitions \(\{P_i\}\) of \(X\) into two sets, each of measure 1/2, such that

1. the partitions \(P_i\) are mutually independent and
2. for each \(i\), \(\mathcal{F}_i = \bigvee_{n=i}^{\infty} P_n\).

It is important to note that in the case that the decreasing sequence of \(\sigma\)-algebras comes from an endomorphism there is no assumption that the \(P_i\) are stationary. (i.e. \(P_i\) is not necessarily \(T^{-1}(P_{i-1})\).) If an endomorphism generates a decreasing sequence of \(\sigma\)-algebras that is isomorphic to the standard dyadic decreasing sequence of \(\sigma\)-algebras then we call that endomorphism **standard**.

Any measure preserving endomorphism \((X, T, \mathcal{F}, \mu)\) also generates an invertible measure preserving automorphism \((\tilde{X}, \tilde{T}, \tilde{\mathcal{F}}, \tilde{\mu})\). We say that the system \((\tilde{X}, \tilde{T}, \tilde{\mu})\) is isomorphic to the (invertible) Bernoulli 2 shift if there exists a partition \(P\) of \(\tilde{X}\) into two sets, each of measure 1/2, such that

1. the partitions \(T^i P\) are mutually independent and
2. \(\tilde{\mathcal{F}} = \bigvee_{n=-\infty}^{\infty} T^n P\).

If a dyadic endomorphism has an invertible extension which is isomorphic to the (invertible) Bernoulli 2 shift then we say the endomorphism is **Bernoulli**.

Both Bernoulliness and standardness are then equivalent to finding a mutually independent sequence of partitions which generate the entire \(\sigma\)-algebra. There is no a priori reason that a standard endomorphism must be Bernoulli or that a Bernoulli endomorphism must be standard as in the case of standardness the partitions must be past measurable but not necessarily stationary and for Bernoulliness they must be stationary but not necessarily past measurable. In this paper we show that in fact neither condition is stronger than the other.
It is already known that standard does not imply Bernoulliness of an endomorphism. Feldman and Rudolph proved in [2] that a certain class of dyadic endomorphisms generate standard decreasing sequences of $\sigma$-algebras. Among these is an endomorphism which Burton showed has a two sided extension which is not isomorphic to a Bernoulli shift [1]. In this paper we construct an endomorphsim that is Bernoulli but the endomorphism is not standard. To complete the picture we mention that the one sided Bernoulli 2 shift is both Bernoulli and standard. The $[T, T^{-1}]$ endomorphism was proved not to be Bernoulli by Kalikow [5] and not to be standard by Heicklen and Hoffman [4].

2 Notation

We begin to introduce some notation to help understand the tree structure of a dyadic endomorphism. Consider a 2-ary tree with $2^n$ nodes or vertices at each index $n \geq 0$. (we will use the words node and vertex interchangably). As we envision the tree bifurcating downward, lower nodes are nodes with higher indices. Each node at index $n$ connects to two nodes at the index $n + 1$. For each pair of nodes which connect to the same node at one level higher we label one of the nodes 0 and the other node 1. This then gives a nontrivial word to $\{0, 1\}$ as a label to each node other than the root as the sequence of values we see along the unique path of nodes from the root to the given node. In this form we can concatenate vertices $v'$ and $v$ by concatenating their labels. Call this labeled tree $\mathcal{T}$. If we truncate the tree at index $n > 0$ we call it $\mathcal{T}_n$.

Let $\eta$ be the set of nodes of $\mathcal{T}$ and $\eta_n$ for $\mathcal{T}_n$. For $v \in \eta$ and at index $i$ (i.e. $v \in \eta_i \setminus \eta_{i-1}$) we write $|v| = i$ and we write $v$ as a list of values $v_1, \ldots, v_i$ from $\{0, 1\}$ where this is the list of labels of the nodes along the branch from the root to $v$. We say that $v'$ is an extension of $v$ if $v' = vv''$ for some $v'' \in \eta$. We also say that $v$ is a contraction of $v'$.

Let $(X, T, \mu, \mathcal{F})$ be a uniformly 2 to 1 endomorphism. Then each $x \in X$ has two inverse images. There exists a measurable two set partition $K$ of $X$ such that almost every $x$ has one preimage in each element of $K$. Label the sets of $K$ as $K_0$ and $K_1$. For each $i \in \{0, 1\}$ and $x \in X$ define $T_i(x)$ to be the preimage of $x$ in $K_i$. We now define a set of partial inverses for $T$. For $v = (v_1, \ldots, v_i) \in \eta$ define $T_v(x) = T_{v_i}(\cdots(T_{v_1}(x))).$ Also define the tree name of $x$ by $\mathcal{T}_x(v) = P(T_v(x)).$ More generally $\mathcal{T}, P$ name $h$ is any function from $\mathcal{T}$ to $P$. For us a subtree of $\mathcal{T}$ will be a path connected set of nodes. Notice that this means a subtree will have a root which is the unique node in it of least index, and will consist of a collection of connected paths descending from this root. If $T'$ is any subtree of $\mathcal{T}$ then
a $T'$, $P$ name $h$ is any function from $T'$ to $P$. A $T'$, $P$ name on a subtree gives rise to a collection of names indexed by intervals in $-\mathbb{N}$ by listing in negative order the names that appear along branches of the subtree (with multiplicities). Be sure to keep in mind that in this translating nodes at index $n$ in the tree correspond to point in $T^\sim$ for the action, i.e. there is a switch in sign. More accurately, such a name on a subtree gives rise to a measure or distribution on such finite names where each name of length $t$ is given mass $2^{-t}$ (again counting multiplicities). If this original tree name is the tree name of a point, then this distribution will be the conditional distribution of the various past cylinders given the path to the root of the subtree.

We say that a node $v$ is in the bottom of the subtree $T'$ if no extension of $v$ is a node in $T'$. We define $T''$, the concatenation of two subtrees $T'$ and $T''$, as follows. Let

$$
\eta_{T''} = \eta_{T'} \cup \bigcup_{v \in \text{bottom of } T'} \eta_{T''(v)}
$$

where the second union is taken over all $v$ which are in the bottom of $\eta_{T'}$. That is to say we attach to each node in the bottom of $T'$ a copy of the subtree $T''$. We concatenate tree names in an analogous manner by extending the labeling of $T$ to be the labeling of $T'$ on each of the copies of $T'$ attached at the bottom of $T$.

Let $\mathcal{A}$ be the collection of all bijections of the nodes of $T$ that preserve the tree structure. We refer to this as the group of tree automorphisms. Let $\mathcal{A}_n$ be the bijections of the nodes of $T_n$ preserving the tree structure. To give a representation to such automorphisms $A$ notice that from $A$ we obtain a permutation $\pi_v$ of $\{0, 1\}$ at each node giving the rearrangement of its 2 immediate extensions. An automorphism of $T_n$ will be represented by an assignment of a permutation of $\{0, 1\}$ to each node of the tree including the root and excepting those at index $n$.

Fix a partition $P$. The Hamming metric between two $T_n, P$ names $W$ and $W'$ is given by

$$
d_n(W, W') = \frac{\# \text{ of } v \in \eta_n \setminus \eta_{n-1} \text{ such that } W(v) \neq W'(v)}{2^n}.
$$

Now define

$$
\bar{v}_n(y, y') = \bar{v}_n^P(y, y') = \inf_{A \in \mathcal{A}_n} (d_n(A(T_y), T_{y'})).
$$

In the case that $\{\mathcal{F}_n\}$ comes from a dyadic endomorphism Vershik's standardness criterion is the following.

**Theorem 2.1** (Vershik) For every finite partition $P$, $\int \bar{v}_n^P(y, y') d\nu \times \nu \to 0$ iff $\{\mathcal{F}_n\}$ is standard [7].
Remark 2.1 A proof of this can also be found in [3].

3 Construction

The construction will be done by cutting and stacking. Cutting and stacking in $\mathbb{Z}$ can be viewed in two ways. One can regard the construction as building a sequence of Rokhlin towers of intervals labeled by symbols from some labeling set $P$. Successive towers are built by slicing up and restacking. In this form the existence of the constructed action follows as one is explicitly defining the map on ever larger parts of the space. One can also view the stack as a distribution on the set of all finite names (most of course given mass zero). For each length $k \in \mathbb{N}$ one can construct a measure on cylinders of length $k$ from each stack by calculating the density of occurrence of that cylinder within the stack. These measures on cylinders will converge weak* to a shift invariant measure on $P^\mathbb{Z}$. The constructed action then is the shift map on $P^\mathbb{Z}$. Usually both these views give the same action although this depends on whether the labels in the first description give a generating partition for the action. For our construction we will follow the latter perspective by constructing names on finite subtrees. We have already described how to translate such a name into a distribution on names on intervals in $-\mathbb{N}$. This translating links our work to the traditional cutting and stacking construction of $\mathbb{Z}$ actions.

The construction will build inductively one $\mathcal{T}_{H(n)}$ name, $B_n$ for each $n$. From this sequence of names we will construct a sequence of measures on $\mathcal{T}_k, P$-names by calculating the density of occurrences of the subtree name within each $B_n$. These measure will converge weak* to a measure on $\mathcal{T}, P$ names. This measure extends to a shift invariant measure on $P^\mathbb{Z}$ and its restriction to $\mathbb{N}$ will be the endomorphism we are interested in. Disjoint occurrences of copies of the name $B_n$ in the past trees of points will place a block structure on these tree names. We consider two points $x$ and $y$ and their $2^m$ inverse images under $(T^{-m})$. The construction will be done in such a way that it will be impossible to find a pairing of the $2^m$ inverse images of $x$ and those of $y$ by tree automorphism that will match up the block structures of the paired inverse images. But there is a bijection of the inverse images which does not preserve the tree structure and which matches up the block structure.

To do the construction we will need three sequences of integers, $H(n)$, the height of $n$ tree, $N(n)$, the number of copies of $n - 1$ trees concatenated to form the $n$ tree, and a parameter $F(n)$. These sequences will be defined inductively. Let $H(1) = 1000$. Given that $H(n - 1)$ has been defined choose $F(n)$ so that $\sqrt{F(n)} > 2^{n+100}H(n - 1)$. Also choose $N(n)$
so that $H(n) = 3F(n) + N(n)H(n - 1) \geq 2^{n+100}F(n)$.

An element of the partition $P$ is of the form $(a, n, v)$, where $a \in \{0, 1\}$, $n \in \mathbb{N}$, and $v \in \eta$. Notice that $P$ will not be a finite partition. Both standardness and Bernoullicity are characterized by the behavior of finite partitions. We will explain how this issue is handled at the appropriate points.

For any $v \in \eta$ define

$$f_n(v) = \text{minimum } \{3F(n), \text{ the smallest } k \text{ such that } \sum_{i=1}^{k} v_i = F(n)\}$$

provided the definition makes sense (i.e. $\sum_{i=1}^{k} v_i \geq F(n)$).

We will now inductively define $T_{H(n)}$. $P$ names which we call $B_n$. The name $B_1$, is defined so that for each vector $v \in \eta_{H(1)}$ gets a distinct label. For any $v \in \eta_{H(1)}$ assign $B_1(v) = (v_{[1]}, 1, v)$.

Now assume that $B_n$ has been defined. Create the subtree that consists of all vectors $v \in \eta_{3F(n)}$ such that $\sum_{i=1}^{k} v_i \leq F(n)$. Give each of these branches a label in $P$ which is not seen in $B_n$. Now concatenate this tree name with $N(n)$ copies of $B_{n-1}$. Then for any branch $v \in \eta_{H(n)}$ which has not yet received a label assign it a label which has not been used before.

To make this precise for any $v \in \eta_{H(n)}$ such that $\sum_{i=1}^{k} v_i < F(n)$ or $|v| > f_n(v) + N(n)H(n-1)$ assign $B_n(v) = (v_{[1]}, n, v)$. If $v \in \eta_{H(n)}$ such that $|v| - f_n(v) \in [1, N(n)H(n-1)]$ let

$$\hat{v_i} = v_i + f_n(v) + \lfloor |v| - f_n(v) \rfloor / H(n-1).$$

Then define $B_n(v) = B_{n-1}(\hat{v})$. This inductively defines $B_n$.

The $T_{H(n)}$ name $B_n$ defines a measure $\mu_n$ on $P_{T_n}^k$, $k \leq H(n)$ as follows. Any $h \in P_{T_n}^k$ receives mass

$$\mu_n(h) = \sum \frac{1}{(H(n) - k + 1)2^{|v|}}$$

where the sum is taken over all $v \in \eta_{H(n)-k}$ such that $h(v') = B_n(vv')$ for all $v' \in \eta_{H(n)-1}$. The measures $\mu_n$ project, as we have described, to measures on names labeled by $[-n, \ldots, -1]$ we still refer to as $\mu_n$. As these measures on names are precisely what would arise if one did traditional cutting a stacking to create the distribution on names associated with $B_n$ we conclude the $\mu_n$ converge in the weak * topology to a shift invariant measure $\hat{\mu}$ on $P_n^\mathbb{Z}$. Restrict $\hat{\mu}$ to $P_n^\mathbb{N}$ to give the endomorphism $T$ we claim is Bernoulli but not standard.

As the labels used to fill in the top and bottom of the tree name only appear there, the block structure on the past trees of points are unique.
Let $K_0$ be the set of $x \in X$ such that $P(x)$ is of the form $(0, *, *)$ and $K_1$ be the set of $x \in X$ such that $P(x)$ is of the form $(1, *, *)$. One sees from the construction that $T : K_0 \to X$ and $T : K_1 \to X$ are both 1-1 and onto. This defines partial inverses $T^{-1}_0$ and $T^{-1}_1$ both of which have constant R.N. derivatives of 1/2 and hence $T$ is a uniformly dyadic endomorphism. By the method described in the previous section we can define $T_v$ for any $v \in \eta$ and $T_v$ for any $x \in X$.

We say that a point $x \in X$ is **in the $n$ block** if there exists $v_x \in \eta_{H(n)}$ such that for all $v' \in \eta_{H(n)-|v_x|}$ we have

$$T_x(xv') = B_n(vv').$$

We say that $x$ is in the **top of the $n$ block** if $|v_x| = 0$. For general tree names we will use the corresponding definitions of being in the $n$ block or being in the top of the $n$ block.

**Lemma 3.1** For any $n \geq 2$ and $k \in [0, H(n-1))$ and $l \geq 3F(n)$ the number of $v \in \eta_k \setminus \eta_{k-1}$ such that $f(v') = k \mod H(n-1)$ is less than $2^{l+1}/H(n-1)$.

**Proof:** It causes no loss of generality to assume that $l = 3F(n)$. The lemma is true because $\sqrt{F(n)} >> H(n-1)$ and the local central limit theorem.

A slightly different version of this lemma is the following.

**Corollary 3.1**

$$\sup_k 2^{-k} \, (# \text{ of } v \text{ such that } |v| = k \text{ and } T_vB_n \text{ is in the top of the } n-1 \text{ block}) \leq 2/H(n-1).$$

**Proof:** It causes no loss of generality to assume that $k \geq 3F(n)$. This is because if $k \leq 3F(n)$ then the quantity we are trying to maximize is greater for $k + H(n-1)$ than for $k$. Then this is just a restatement of the previous lemma.

4. The sequence of $\sigma$-algebras is not standard

Let $\epsilon_1 = 1$ and $\epsilon_n = \epsilon_{n-1}(1 - 2^{-n-\delta})$. Choose $\epsilon = \lim \epsilon_n > 0$. The main part of the proof that $(X, T, \mu)$ does not generate a standard decreasing sequence of $\sigma$-algebras is the following inductive statement.

**Lemma 4.1** Given any $n \in \mathbb{N}$, $v \in \eta_{H(n)} \setminus \eta_{3F(n)}$, and $j$, $0 < j \leq H(N) - |v|$, we have

$$\bar{v}_j(T_vB_n, B_n) > \epsilon_n.$$
Before we start the proof of this lemma we will sketch the proof and introduce some notation. We argue by induction in \( n \). The main idea is to break up the sum in the calculation of \( \bar{v}_j(T_v B_n, B_n) \) into the weighted average of terms of the form \( \bar{v}_k(T_{v'} B_{n-1}, B_{n-1}) \). The variation in the value of \( f_n \) will ensure that for most of the terms being averaged \( |v'| > 3F(n - 1) \). Arguing inductively in \( n \) we will bound \( \bar{v}_j(T_v B_n, B_n) \) in terms of values \( \bar{v}_k(T_{v'} B_{n-1}, B_{n-1}) \). Now we introduce notation to make this precise.

Given \( n \in \mathbb{N} \), \( v \in \eta_{H(n)} \), \( j \in \mathbb{N} \) such that \( 0 < j \leq H(n) - |v| \), and \( A \in \mathcal{A}_j \), we will define a few subsets of \( \eta_j \). First let \( V_1 \) be all \( \tilde{v} \in \eta_j \setminus \eta_{j-1} \) such that \( T_{v\tilde{v}} B_n \) is not in the \( n - 1 \) block or \( T_{A(\tilde{v})} B_n \) is not in the \( n - 1 \) block.

Let \( V_2 \) be all \( \tilde{v} \in \eta_j \) such that

1. either \( T_{v\tilde{v}} B_n \) or \( T_{A(\tilde{v})} B_n \) is in the top of an \( n - 1 \) block,
2. no extension of \( \tilde{v} \in V_1 \),
3. there is no \( \tilde{v}'' \in \eta_j \) such that \( \tilde{v}'' \) is an extension of \( v \) and \( T_{v\tilde{v}''} B_n \) is in the top of an \( n - 1 \) block, and
4. there is no \( \tilde{v}'' \in \eta_j \) such that \( \tilde{v}'' \) is an extension of \( A(\tilde{v}) \) and \( T_{\tilde{v}''} B_n \) is in the top of an \( n - 1 \) block.

Now for each \( v \in \eta_j \setminus \eta_{j-1} \) either \( v \in V_1 \) or \( v \) has exactly one contraction in \( V_2 \). But both can not happen. From this it is easy to verify that

\[
\frac{1}{2^j} (\# \ of \ \tilde{v} \in V_1) + \sum_{\tilde{v} \in V_2} 2^{-|\tilde{v}|} = 1
\]  

(1)

and

\[
d_j(T_v B_n, A(B_n)) = \frac{1}{2^j} (\# \ of \ \tilde{v} \in V_1 \ such \ that \ P(T_{v\tilde{v}} B_n) \neq P(T_{v/A(\tilde{v})} B_n)) + \sum_{\tilde{v} \in V_2} 2^{-|\tilde{v}|} d_j(\tilde{v}, (T_{v\tilde{v}} B_n, A(\tilde{v})))
\]  

(2)

We used the notation \( A_{\tilde{v}} \) to denote the restriction of \( A \) to \( \tilde{v}_{(n-|\tilde{v}|)} \).

Since one of \( T_{v\tilde{v}} B_n \) or \( T_{v/A(\tilde{v})} B_n \) is in the top of an \( n - 1 \) block we can almost use the induction hypothesis to get a bound on the summands in line 2. Suppose it is \( T_{v\tilde{v}} B_n \) that is in the top of an \( n - 1 \) block. In order to apply the induction hypothesis we just need to make sure that \( T_{v/A(\tilde{v})} B_n \) is not in the top \( 3F(n - 1) \) levels of the \( n - 1 \) block.
Now we define sets $V_3$ and $V_4$ so that $V_2$ is the disjoint union of $V_3$, where the induction hypothesis applies, and $V_4$, where it does not. Let $h$ be the largest $k \leq j$ such that $|v| + k - f_n(v) = 0 \mod H(n-1)$. Let $V_3$ consist of all $\tilde{v} \in V_2$ such that

1. $T_{v\tilde{v}}B_n$ is in the top of the $n - 1$ block and $(h - f_n(A(\tilde{v}))) \mod H(n-1) > 3F(n-1)$ or

2. $T_{A(\tilde{v})}B_n$ is in the top of the $n - 1$ block and $|A(\tilde{v})| - h > 3F(n-1)$

Let $V_4 = V_2 \setminus V_3$.

**Lemma 4.2** Given $n$ and let $v \in \eta_{H(n)} \setminus \eta_{3F(n)}$. Then for any $j \leq H(n) - |v|$ we have

$$\frac{1}{2^j} (# of \tilde{v} \in V_1) + \sum_{\tilde{v} \in V_3} 2^{-|\tilde{v}|} > 1 - 2^{-n-95}.$$

**Proof:** By line 1 this is equivalent to showing that

$$\sum_{\tilde{v} \in V_4} 2^{-|\tilde{v}|} < 2^{-n-95}.$$

If $T_{v\tilde{v}}B_n$ is in the top of the $n - 1$ block then $|\tilde{v}| = h$. The number of $\tilde{v}$ with $|\tilde{v}| = h$ and $(h - f_n(A(\tilde{v}))) \mod H(n-1) \leq 3F(n-1)$ is

$$\leq (3F(n-1) + 1) \sup_k \# of v' \in \eta_j \setminus \eta_{j-1} such that f_n(v') = k \mod H(n-1)$$

$$\leq 4F(n-1)2^k \frac{2}{H(n-1)}$$

$$\leq 2^k \frac{8F(n-1)}{H(n-1)}.$$

The sum $\sum 2^{-|A(\tilde{v})|}$ over all $\tilde{v}$ such that $T_{A(\tilde{v})}B_n$ is in the top of the $n - 1$ block and $0 \leq |A(\tilde{v})| - h \leq 3F(n-1)$ is

$$\leq (3F(n-1) + 1) \sup_k 2^{-k} (# of \tilde{v} such that |\tilde{v}| = k and T_{\tilde{v}}B_n is in the top of the n - 1 block)$$

$$\leq 4F(n-1) \frac{2}{H(n-1)}$$

$$\leq \frac{8F(n-1)}{H(n-1)}.$$
Thus combining these two estimates gives

\[
\sum_{i \in \mathcal{V}_4} 2^{-|\alpha|} \leq 2^{n_0} \cdot \frac{8 F(n - 1)}{H(n - 1)} + \frac{8 F(n - 1)}{H(n - 1)} \\
\leq (16) 2^{-n - 99} \\
\leq 2^{-n - 95}.
\]

Proof of Lemma 4.1: The base case is trivial. This is because if \( v \neq v' \) then \( B_1(v) \neq B_1(v') \).

For any automorphism \( A \)

\[
d_j(T_v B_n, A(B_n)) = \frac{1}{2j}(\text{# of } \tilde{v} \in \mathcal{V}_1 \text{ such that } P(T_{v\tilde{v}} B_n) \neq P(T_{v' A(\tilde{v})} B_n)) \\
\sum_{i \in \mathcal{V}_3} 2^{-|\alpha|} \Big( T_{v, \tilde{v}} B_n, A_\tilde{v}(T_{v, A(A(\tilde{v}))) B_n}) + \\
\sum_{i \in \mathcal{V}_4} 2^{-|\alpha|} \Big( T_{v, \tilde{v}} B_n, A_\tilde{v}(T_{v, A(A(\tilde{v}))) B_n})
\]

\[
\geq \frac{1}{2j}(\text{# of } \tilde{v} \in \mathcal{V}_1) + \sum_{i \in \mathcal{V}_3} 2^{-|\alpha|} \Big( T_{v, \tilde{v}} B_n, A_\tilde{v}(T_{v, A(A(\tilde{v}))) B_n}) \quad (3)
\]

\[
\geq \frac{1}{2j}(\text{# of } \tilde{v} \in \mathcal{V}_1) + \sum_{i \in \mathcal{V}_3} 2^{-|\alpha|} \inf_{3F(n-1) \leq H(n-1)} \tilde{v}_{j, \tilde{v}} (B_{n-1}, T_{v, \tilde{v}} B_{n-1}) \cdot (4)
\]

\[
\geq \epsilon_{n-1} \frac{1}{2j}(\text{# of } \tilde{v} \in \mathcal{V}_1) + \epsilon_{n-1} \sum_{i \in \mathcal{V}_3} 2^{-|\alpha|}
\]

\[
> \epsilon_{n-1}(1 - 2^{-n-95})
\]

\[
> \epsilon_n.
\]

Line 3 is true because if \( \tilde{v} \in \mathcal{V}_1 \) then either \( T_{v \tilde{v}} B_n \) is not in the \( n-1 \) block or \( T_{A(\tilde{v})} B_n \) is not in the \( n-1 \) block. Since \( v \tilde{v} \neq A(\tilde{v}) B_n(v \tilde{v}) \neq B_n(A(\tilde{v})) \).

Line 4 is true because one of \( T_{v \tilde{v}} B_n \) or \( T_{A(\tilde{v})} B_n \) is in top of the \( n-1 \) block by the definition of \( \mathcal{V}_2 \). The induction hypothesis applies because of the definition of \( V_3 \). As the above calculation is independent of \( A \) we have a bound on \( \tilde{v} \).

Now we are ready to prove that \( \int v^p_n(y, y') dv \times \nu \neq 0 \).
Lemma 4.3 For all $n$ there exists $X_n$ and $Y_n$ with $\mu(X_n), \mu(Y_n) > 1/5$ with the following property. For any $x \in X_n$ and any $y \in Y_n$

$$\tilde{\nu}_{H(n-1)}(\mathcal{T}_x, \mathcal{T}_y) \geq \epsilon.$$ 

Proof: If a point $x$ is in the $n$ block then we get a vector $v_x$. Define

$$X_n = \{x \mid |v_x| - f_n(v_x) \mod H(n - 1) \in (H(n - 1)/8, 3H(n - 1)/8)\}.$$ 

Define

$$Y_n = \{y \mid |v_y| - f_n(v_y) \mod H(n - 1) \in (5H(n - 1)/8, 7H(n - 1)/8)\}.$$ 

Given $x \in X_n$ and $y \in Y_n$ let $k = H(n - 1) - [|v_x| - f_n(v_x) \mod H(n - 1)]$. Now

$$\tilde{\nu}_{H(n-1)}(\mathcal{T}_x, \mathcal{T}_y) \geq \inf_{A \in A_k} \frac{1}{2^k} \sum_{|v| = k} \tilde{\nu}_{H(n-1)-k}(T_{\nu}(\mathcal{T}_x), T_{A(v)}(\mathcal{T}_y)).$$

By the choice of $k$ all the $\tilde{\sigma}$ terms are of the form $\tilde{\nu}_{H(n-1)-k}(B_{n-1}, T_{v''}B_{n-1})$ with $v'' \in \eta_{H(n-1)} \setminus \eta_{H(n-1)/4}$. Thus

$$\tilde{\nu}_{H(n-1)}(\mathcal{T}_x, \mathcal{T}_y) \geq \inf \tilde{\nu}_{H(n-1)-k}(B_{n-1}, T_{v''}B_{n-1}) \geq \epsilon,$$

where the inf is taken over all $v'' \in \eta_{H(n-1)} \setminus \eta_{H(n-1)/4}$. The last inequality is by lemma 4.3. By the definition of $F(n)$ and $H(n)$ we get

$$\mu(X_n) = \mu(Y_n) \geq \frac{1}{4} \mu(B_{n-1}) \geq \frac{1}{4} \prod_{j \geq n} \frac{3F(j)}{H(j)} \geq \frac{1}{5},$$

which proves the lemma.

Theorem 4.1 $(X, T, \mu)$ does not generate a standard decreasing sequence of $\sigma$-algebras.

Proof: From lemma 4.3 it follows that for all $n$

$$\int v_{H(n)}^P(y, y') \, d\nu \times \nu > \epsilon/25.$$ 

Thus

$$\int v_{j}^P(y, y') \, d\nu \times \nu \neq 0.$$
Now choose a finite partition $P'$ which agrees with $P$ on all but $\epsilon/100$ of the space. Then it is clear that for all $n$

$$\int v_{H(n)}^{P'}(y, y')d\nu \times \nu > \epsilon/50$$

and

$$\int v_j^{P'}(y, y')d\nu \times \nu \not\rightarrow 0.$$ 

Thus by theorem 2.1 $(X, T, \mu)$ does not generate a standard decreasing sequence of $\sigma$-algebras. 

\section{The two sided extension is Bernoulli}

This is proven by showing that $(T, P)$ is v.w.B. Of course v.w.B. is a condition on finite partitions but if one verifies it for a countable partition it still implies Bernoullicity. We will use the same techniques used by Ornstein in [6]. For any $v = (v_1, ..., v_k)$ and any $i \leq k$ let $v|_i = (v_1, ..., v_i)$. Also let $v^i| = (v_{i+1}, ..., v|_{n|})$. Thus $v = v|v^i$. For a fixed $n$ and any $v_1 \in \eta$ let $S_{v_1}$ be all extensions $v'$ of $v_1$ such that $|v'| = |v_1| + l_n$ where $l_n$ is a number defined below. The crux of the proof is the following matching lemma.

\begin{lemma}
For all $n$ and $k \leq n$ there exists $V \subset \eta_{H_n}$ and $l_n \in N$ with the following property. Then for any $v_1, v_2 \in V$ there exists a one to one map $M : S_{v_1} \rightarrow S_{v_2}$ such that

$$\sum_{v \in S_{v_1}} \{ \text{# of } i \text{ such that } T_{v|_{i+1}^{i+1}}B_n \text{ is in the top of the } n - k \text{ block and } T_{v|_{i+1}^{i+1}}B_n \text{ is in the top of the } n - k \text{ block} \} \geq 2^{l_n} l_n - 2H(n - 1)H(n - k)\mu(B_{n-k})(1 - (9/10)^{k-1}).$$

\end{lemma}

\textbf{Proof:} Fix $n$ and the proof is by induction on $k$. Let $V = \eta_{H(n) - l_n - 3F(n)} \setminus \eta_{3F(n)}$ where $l_n = H(n)/2^n$. For $k = 1$ the statement is vacuously true.

Note that by the previous section $M$ cannot preserve the tree structure. Along with any $v \in S_{v_1}$ there is a corresponding sequence in $P^{\nu}$. It is defined by $v_k = (B_{n_1}(v|_{k+1}^{k+1}), ..., B_{n_k}(v|_{k+1}^{k+1}))$. For a given $v \in S_{v_1}$ we say that the $j$ blocks are the intervals of the form $[i, i + h(j)]$ which are contained in $[1, l_n]$ and $T_{v|_{i+1}^{i+1}}$ is in the top of the $j$ block. It causes no loss of generality to assume that the extensions of $v_1$ and $v_2$ have the same number $n - 1$ blocks. We will show we can choose $M$ to have the following property. If the sequences corresponding to
two vectors in $S_{n_1}$ disagree only inside $n - k$ blocks in $n - 1$ blocks then $M$ applied to these vectors yields two vectors whose corresponding sequences differ inside $n - k$ blocks inside of $n - 1$ blocks. (i.e. If $(n_v) = (n_{v'})$ for all $i$ inside $n - k$ blocks inside $n - 1$ blocks of $v$ then $(n_{M(v)}) = (n_{M(v')})$ for all $i$ inside $n - k$ blocks inside $n - 1$ blocks of $M(v)$.)

Consider $v \in S_{n_1}$ and all other $v'$ such that $(n_v) = (n_{v'})$ for all $i$ inside $n - k$ blocks inside $n - 1$ blocks of $v$. We now describe how to modify $M$ on this set. When we apply this procedure to all such sets we get $M$ such that the induction hypothesis holds for $k + 1$.

Now consider the $n - k$ blocks of $v$ that are not the same as some $n - k$ block of $M(v)$. Pair these with the $n - k$ blocks of $M(v)$ that are not the same as some $n - k$ block of $v$ in such a way that the overlap of paired blocks is at least $1/3$ of the length of these blocks.

Now pick one pair of $n - k$ blocks. Say one of them is $[i, i + H(n - k)]$ and the other is $[j, j + H(n - k)]$. Choose $M'$ so that the number of $v'$ in this set with

$$(i + f_{n-k}(v'|)) - (j + f_{n-k}(M'(v'|))) = 0 \mod H(n - 1)$$

is maximized. This can be done for at least half of the $v'$ in the set since since $\sqrt{F(n - k)} >> H(n - k - 1)$. Now repeat this procedure for the other paired $n - k$ blocks. Then repeat this procedure for another $v$. Doing this we have matched at least $1/10$ of the $n - k - 1$ blocks inside the unmatched $n - k$ blocks which justifies the induction hypothesis for $k + 1$.

\[ \]

**Theorem 5.1** The transformation $(\tilde{X}, T, \tilde{\mu})$ is isomorphic to the Bernoulli 2 shift.

**Proof:** Since $(X, T, \mu)$ is dyadic and has entropy log 2 we need only to show that $(\tilde{X}, T, \tilde{\mu})$ is very weak Bernoulli. It also suffices to show that $(\tilde{X}, T^{-1}, \tilde{\mu})$ is very weak Bernoulli.

Given $\epsilon$ choose $n$ and $k$ so that

$$2^{n(9/10)}k^{-1} + (1 - \mu(B_{n-k})) + \frac{2H(n - 1)}{l_n} < \epsilon$$

and

$$\frac{3F(n) + l_n}{H(n)}\mu(B_n) > 1 - \epsilon.$$ 

Let $G$ be the set of all $x$ such that $x$ is in the $n$ block and $v_x \in V_n$. Then

$$\mu(G) = \frac{3F(n) + l_n}{H(n)}\mu(B_n) > 1 - \epsilon.$$ 

Now given any $x, x' \in G$ we get $v_x, v_{x'} \in V_n$. Now choose $M$ so that

1. the conclusion of the previous lemma is satisfied and

13
2. so that if \( M(v) = v' \) and \([i, i + H(n - k)]\) is an \( n - k \) block for both \( v \) and \( v' \) then 
\[(n_v)_j = (n_{v'})_j \] for all \( j \in [i, i + H(n - k)]\).

Now the fraction on \( n - k \) blocks inside \( n - 1 \) blocks that are unmatched is at most \((9/10)^{k-1}\).

The fraction of an \( n - 1 \) block that is not part of \( n - k \) blocks is less than \((1 - \mu(B_{n-k}))\).

While the fraction of \([1, l_n]\) that is not in an \( n - 1 \) block is at most \(\frac{2H(n-1)}{l_n}\). Thus

\[
\frac{1}{2^n l_n} \sum_{v \in S(v)} \# \text{ of } i = [1, l_n] \text{ such that } (n_v)_i \neq (n_{M(v)})_i \\
\leq (9/10)^{k-1} + (1 - \mu(B_{n-k})) + \frac{2H(n-1)}{l_n} < \epsilon.
\]

Thus \( T^{-1} \) is very weak Bernoulli.
